5 **CONTACT HOLE PROFILE AND LINE EDGE WIDTH METROLOGY**
 FOR CRITICAL IMAGE CONTROL AND FEEDBACK OF
 LITHOGRAPHIC FOCUS

10 **DESCRIPTION**

10 **Field of the Invention**

The present invention broadly relates to an improvement in wafer semiconductor printing in the field of photolithography. More particularly, it relates to a method of maintaining optimum focus through a process control system that uses a control algorithm translating Critical Dimension (CD) and line edge width measurements into a corresponding focus adjustment which is fed back to an exposure tool.

20 **Background of the Invention**

In the field of integrated circuits (ICs), photolithography is used to transfer patterns, i.e. images, from a mask containing circuit-design information to thin films on the surface of a substrate, e.g. Si wafer. The pattern transfer is accomplished with a photoresist (e.g., an ultraviolet light-sensitive organic polymer). In a typical image transfer process, a substrate that is coated with a photoresist is illuminated through a mask and the mask pattern is transferred to the photoresist by chemical developers. Further pattern transfer is accomplished using a chemical etchant. In current technologies, this masking process usually is repeated multiple times in the fabrication of an integrated circuit.

30 Fig. 1 illustrates a typical photolithographic processing (fab) environment comprising a mask 110, a stepper device 120 with lens 130 through which the exposure energy 140 is focused on a wafer 150 coated with a photoresist 160.

5 It is well known in the field of photolithography that Critical Dimension may change as a
result of either effective exposure or tool focus. Prior art tool focus control monitoring
and feed back is achieved by imaging a specific image design on non-patterned test
wafers with individual exposure fields stepped through a range of z focus. It is a well
known practice to define the center of the focus step range yielding the best image CD
10 stability as the nominal tool focus. This image stability has, in the past, either been
subjectively determined by reading focus "dots" under a microscope or by measuring a
change in 2 dimensional line width on a pattern such as a photoresist chevron or
measuring the foreshortening of a series of lines and spaces. The result of this prior art
method is that an offset from this nominal tool focus to product focus of a specific
15 masking level must be controlled by implementing a table of run rules, as shown in Fig.
13. In the table of run rules, the focus 1370, default exposure 1360, are related to the tool
1310, technology 1320, wafer part number 1330 and process 1340. Under the prior art
method, the optimal product focus offset is a fixed offset. It is well known in the
industry, however, that for a given photolithographic exposure tool, there is variability of
20 nominal tool focus. Thus, optimal product focus offset is variable as a result of the
inherent tool focus variation. This prior art technique has thus required that two
dimensional critical dimension be monitored on product masking levels so that shifts in
CD are compensated for by feeding back a change in dose to the exposure tool. As
discussed below, the related art has not solved the problem of real time variation in
25 optimal product focus offset due to photolithographic exposure tool nominal focus
instability.

A related art technique for across field dimensional control in a microlithography tool is
described in Borodovsky (U.S. Patent No. 6,021,009) which is directed to a lithography
30 tool adjustment method through which light intensity is varied to reduce line width
variations. This process however, does not measure critical features to determine a z

5 focus parameter, nor does it differentiate between feature error components due to focus shift and other process factors.

10 Another related art method is described in Lai (U.S. Patent No. 6,190,810 B1) which utilizes a single spot laser focusing system in which the laser light spot is always positioned between a series of registration marks. However, Lai does not teach the use of critical design features, i.e. line edge width (EW) and contact hole profile, for z focus control.

15 Another related art technique described in Marchman (U.S. Patent No. 5,656,182) utilizes feedback control, however, Marchman does not address attainment of the optimum CD, given tool configuration, calibration, and specification values. Rather it merely performs stage position control as a function of the latent image produced in the substrate.

20 A further related art technique described in Tadayoshi (JP 6294625 A) discloses a laser beam microscope means for determining the dimensions and profile of a resist pattern but does not disclose analysis of the profile information for z focus control of a photolithographic exposure tool.

25 Similarly, a related art technique described in Atsushi (JP 11186132 A) discloses resist pattern width measurements to determine an allowable exposure dose range. This disclosure, however does not address the issue of using 3 dimensional resist measurements to feedback a focus bias or to differentiate between a lithography tool focus shift and other process factors.

30 While the technique of using feedback control using 2 dimensional metrology to overcome a shift in critical dimension due to exposure variation is known in the art, there

5 remains a need in the art for the capability to compensate for tool focus variation directly on product.

It would thus be highly desirable to provide a system and method for independently controlling the variation in optimal product focus offset due to instability in the
10 photolithographic exposure tool, thus obviating the above-mentioned drawbacks of related art techniques.

It would be further highly desirable to provide a system and method of compensating for variation in optimal product focus offset, i.e., correcting focus errors, of a
15 photolithographic exposure tool implementing a production or similar reticle, using a production wafer, and particularly, a system and method that provides CD control by successfully predicting z focus and x and y tilt, while isolating the focus control in the exposure tool from other factors.

20 **SUMMARY OF THE INVENTION**

Therefore, it is an object of the present invention to provide a photolithographic system and method that provides for focus feedback corrections independently of dose to maintain critical dimension control.

25 Another object of the present invention is to provide the capability for determining directly on a product image if a change in monitored CD is a function of lithography tool z focus shift, x/y tilt shift, or a change in effective exposure or resist sensitivity.

30 A further object of the present invention is to provide the capability for correcting lithographic z focus variation and/or x/y tilt shifts when detected.

5 These and other objects and advantages may be obtained in the present invention by providing a method for monitoring 3-dimensional contact hole profile changes and 3-dimensional line Edge Width (EW) changes in a photo sensitive film and feeding back compensatory exposure tool focus/tilt corrections to maintain a stable lithographic process.

10

Specifically, according to a first aspect of the invention, there is provided a method of controlling focus and x/tilt errors of a photolithographic exposure tool which comprises:: making feature measurements of three dimensional profile changes in a photosensitive resist; storing the feature measurements; generating a function defining a relationship
15 between the feature measurements and focus of the photolithographic exposure tool; and, computing from the function a best profile. The method may also be implemented in a system comprising the photolithographic exposure tool and computer.

Additionally, the present invention uses empirically derived relationships with 3
20 dimensional feature measurements for z focus and x/y tilt control. The offset between nominal tool focus and product best focus for a specific masking level is hereinafter referred to as optimal product focus offset. Moreover, this optimum product focus offset per level varies with parameters such as the masking level, specific resist and arc thickness, exposure illumination type and reticle design (Chrome On Glass, i.e., COG vs.
25 Attenuating Phase Shift Mask, i.e., ATPSM, etc).

According to another aspect of the invention, there is provided a system and method comprising the steps of: making feature measurements of three dimensional profile changes in a photosensitive resist; storing the measurements; generating a function which
30 defines a relationship between the feature measurements and the focus of the photolithographic exposure tool; and, computing from said function x/y tilt values wherein the x/y tilt values are used to control the exposure tool thereby achieving an

5 optimum x/y tilt offset. The wafer is then printed at the optimal product focus offset and optimum x/y tilt offsets determined by the inventive steps, thereby improving critical product image quality.

Brief Description of the Drawings

10

The present invention, which provides a method of photolithographic exposure tool focus, will now be described in more detail by referring to the drawings that accompany the present application. It is noted that in the accompanying drawings like reference numerals are used for describing like and corresponding elements thereof.

DETAILED DESCRIPTION OF THE INVENTION

20 In the following description, the best profile computed from the function is defined to be the optimal product focus offset. In practice the best profile and optimal product focus offset may not be identical because of asymmetry of the overall process window, which results in a bias added to best profile in order to obtain optimal product focus offset. Z focus errors measured using the first aspect of the invention are used to determine the
25 change from the optimal product focus offset, which are then fed back to the exposure tool.

In view of Fig. 1, a mask, i.e. reticle, 110, with critical design features representing a process and level for a target critical dimension is placed in a stepper tool 120. The
30 stepper tool is used to project a design pattern 115 from the mask, i.e., reticle 110 onto and exposing a photoresist layer 160 that coats semiconductor wafer 150. A photoresist treated wafer, typically a focus expose matrix wafer is mounted on the tool in preparation

5 for various calibration field exposures. Field exposures are made across the rows and down the columns of the focus expose matrix wafer. Either during the field exposures, or after the field exposures have been completed, 3 dimensional profile measurements of the design features, which have been transferred to the resist, are made and recorded for data processing.

10

Figure 1A, at steps 173-179 represents a functional diagram depicting the product manufacturing set up calibration as practiced by a preferred implementation of the present invention. The prior art calibration as shown in 172 uses Bossung plots along with two dimensional critical dimension measurements to determine an optimal product focus offset. The optimal product focus offset is determined by locating the flat points, i.e. minimum or maximum on the Bossung plots as shown in Figs. 1D, 2, 3 and 4. As known in the art, Bossung plots may be used in the tool calibration process to determine a nominal CD or focus. The Bossung plot 190 of Fig. 1D shows line CD as a function of focus for various exposure values. The Bossung plot 300 of Fig. 2 shows space dimension change as a function of focus over a range of exposure values. Note that in both the Fig. 1D and Fig. 2 plots, the curves trend to a flat part, i.e. minimum 185 for Fig. 1D and a maximum 320 for Fig. 2. From an inspection of either Bossung plot it is seen that this trend towards a minimum or maximum is independent of exposure levels. Either plot may be used to determine a nominal exposure by determining the flat part of the curves. Thus, in both Bossung plots, the flat part of the curves trend over a focus of -0.100 μ m. That focus value being a nominal focus, i.e., optimal product focus offset, represents the center of the process window for the exposure tool. The exposure is then selected that yields the required critical dimension (CD) for the technology to be processed on the wafer. For example, as shown in Fig. 1D, at a focus of -0.100 μ m, and 0.17 μ m line CD, the energy level of 22.5 mJ/cm² should be used as indicated at maze line 195. That is, the nominal focus is chosen by selecting the dose, i.e., exposure, giving the required critical dimension at a focus position with the flattest CD response to that

5 dose, for example, Fig. 1D focus line at 185 and Fig. 2 focus line at 320. The deficiency
in this prior art technique is that it does not include a calibration method that can be used
against measurements made on product, i.e., a production wafer, during the production
phase to correct for tool focus variability. The inventive method of steps 173-179
overcome this problem by providing a calibration tool against which three dimensional
10 feature measurements, e.g., edge width or contact hole profile, made on product during
the production phase may be used to correct tool focus errors with respect to the optimal
product focus offset. Fig. 1C depicts the variety of ways a line EW or contact hole
profile measurement is taken. As shown in Fig. 1C i) an in focus imaged resist line
scanned by a scanning electron microscope (SEM) reveals a relatively small line edge
15 width 162 compared to the cross sectional line width 161 of the scanned line. At Fig. 1C
ii) the defocus is revealed by a relatively large edge width 163 vs. the cross sectional line
width 164 of the scanned line. As shown in Fig. 1C iii) an in focus imaged resist hole is
shown to have a steep profile 165 going from the top to bottom of the hole, and in Fig.
1C iv), the defocused imaged resist hole has a relatively shallow top to bottom profile
20 grade 166. As shown in Fig.3, indicated by line 330, the location of optimal product
focus offset can be identified on the line edgewidth versus focus curve, in which the
relationship is sensitive to focus, but is independent of exposure dose.

This independence from exposure level can be used to determine whether a change in
25 critical dimension is the result of exposure variations or tool variations, such as focus or
x/y tilt. For example, if the 3D profile shows little or no change across extreme field site
measurements, while 2D critical dimension has significantly greater change, then that
change is attributable to exposure variations and may be adjusted accordingly. Otherwise,
if a significant change in, for example, line edge width (a 3D independent measurement
30 of focus) is observed across extreme field site measurements, then an appropriate focus
adjustment may be made. Although the 3 dimensional measurements such as line edge
width or contact hole profile represent independent measurements of tool focus, it has

5 been shown that minimizing across field variation in edge width or contact hole profile also lowers the overall range of the critical dimensions, thereby additionally improving across the field line width variations (AFLV).

10 Figures 5 and 6 show the relationship between CD and EW for the extreme positions in the exposure field. It is observed that, for example as shown in Fig. 6, the right field line edge width variation at 604 and 602 is smaller than the left field line edge width variation at 603 and 601. As shown in Fig 5 the right field CD variation at 504 and 502 is smaller than the left field CD variation at 503 and 501. Thus the CD variations correlate with the EW variations, and selecting focus and tilt values that minimize EW variations, as is done
15 in the present invention, results in an across field improvement in CD.

Returning to Fig. 1A at steps 173 through 179, the steps as discussed below may be performed by a suitably programmed computer. As shown at step 173, for a given masking level, resist, arc thickness, exposure illumination type and reticle design, a focus
20 exposure wafer is created under varying focus and exposure energy conditions across the wafer. Edge width (EW) is then measured for each focus/exposure condition or variant at step 174. EW vs. focus for each exposure level is then plotted at step 175. A nominal exposure, i.e., nominal energy level, is selected. This nominal exposure may be determined from a Bossung plot such as shown in either Fig. 1D or Fig. 2. Alternatively,
25 the nominal exposure may be determined from a table of run rules such as illustrated in column 1360 of Fig. 13. Once the nominal exposure, i.e. default exposure level, has been selected, edge width vs. focus data at that nominal exposure level may be extracted from the recorded measurement data. Thus, a plot of edge width (EW) vs. focus, for each exposure level is created from the data collected and plotted at steps 174, 175. At step
30 176, a curve which corresponds to the default exposure level is fitted to the plot of step 175. This curve, known as a calibration curve, may be determined by using well known mathematical techniques, such as a least squares polynomial method, and results in a

5 function comprising at least a 3rd order, e.g., cubic equation. At step 177 an inflection point of the calibration curve is then located where the second derivative of the function is equal to zero. This point denotes the best profile for the critical feature, as shown in step 178. As shown in step 179, the best profile corresponds with and is equal to the prior art calculated optimal product focus offset discussed above. Referring now to Fig. 8,
10 therein is illustrated a representative calibration curve 805 with its respective inflection point 806 fitted to the raw data points 802. Mathematically, the inflection point 806 is found by solving the equation, $y'' = 0$ (where the function $y = Ax^3 + Bx^2 + Cx + D$, represents the calibration curve, and necessarily, $y'' = 6Ax + 2B$). Thus, solving the equation $6Ax + 2B = 0$ for x , where $x = -1/3(B/A)$, results in the best profile, i.e.,
15 optimal product focus offset. The edge width corresponding to optimal product focus offset is then located on the calibration curve in Fig. 8. This value of edge width represents the target EW for a particular photolithographic exposure tool and process. Note that the optimal product focus offset, as calculated by the preferred implementation of the present invention is based on the empirical relationship between EW and tool focus
20 offset, i.e. the calibration curve 805 created as shown in Fig. 8. Additionally, the calibration curve 805 may be used along with three dimensional measurements made on product, i.e., a production wafer, during manufacturing to determine a measured focus which, if different from the optimal product focus offset, represents a bias from the optimal product focus offset which may then be feedback to the photolithographic
25 exposure tool, correcting z focus for a future lot of product.

Figure 1B is a functional diagram depicting the product manufacturing process steps 200-210 of the present invention. All of the subsequent steps discussed below may be performed manually, or automatically by a suitably programmed computer. As shown in
30 Fig. 1B at step 200, EW and CD measurements are taken at multiple points across the exposure field for a specific feature type, e.g., line or contact hole. Measurement data is

5 collected and grouped by process and lithography tool as indicated at step 201. A database may be used to store this measurement data.

At step 202, a calculated average left EW and average right EW is used as an EW point for a given focus. This represents an average edge width by exposure field. At step 203 a
10 z focus, Z_m , i.e., a measured focus, is determined from the average measurements of step 202. The EW vs. focus, i.e., calibration curve (805 Fig. 8) is used for this determination. The average EW corresponding to step 202 is located on the calibration curve, the corresponding focus is the measured focus, Z_m . Because the calibration curve is independent from exposure dose variations, any difference, i.e., bias, of Z_m from the
15 optimal product focus offset at step 179, Fig. 1A, represents a tool focus variation which should be corrected. This bias, referred to as Z_{bias} , is calculated at step 204. If the bias exceeds a predetermined number, then the current job, i.e., lot under which the measurements 200 were taken is reworked at step 210. Otherwise Z_{bias} is fed back as a z focus correction to the lithographic tool for application to subsequent process lots at step
20 205.

In a preferred embodiment, this calculation is carried out by computer (Fig. 14, 1410), typically the same computer that manages the data collection, data storage, plotting and curve fitting discussed above.

25 In a similar manner, the preferred implementation of the present invention calculates, then applies x/y tilt corrections to a photolithographic exposure tool. As shown in Figs. 7 and 9, the relationship between average upper focus 901 and average lower focus 902 corresponds to the relationship between average upper EW 701 and average lower EW
30 702, and may be used to derive a y-axis or "y" tilt. Similarly, the relationship between average right focus 904 and average left focus 903 corresponds to the relationship between average right EW 703 and average left EW 704 and may be used to derive an x-

5 axis or "x" tilt. Referring to Fig. 1B at steps 206 through 209, it is shown that in a similar manner as described herein, the x/y tilt may be optimized by using the 3D profile measurement changes vs. extreme exposure field positions and, a trigonometric relationship between the measurements and exposure field positions. Assuming that the measurement, grouping and storing steps of Fig. 1B at steps 200, 201 have already been performed, the changes in edge width in the x direction corresponding to right – left edge width changes are calculated at step 206, and the changes in edge width in the y direction corresponding to upper – lower edge width changes are calculated at step 207. As shown in Fig. 7, these measurements are then averaged to include an average upper EW, an average lower EW, an average left EW, and an average right EW to aid in determining an actual x/y tilt of the exposure field plane. In Fig. 1B at step 208, the average EW's of Fig. 7 are then used in conjunction with the edge width vs. focus calibration curve of Fig. 8 to derive an average upper focus, average lower focus, average right focus, and average left focus.

20 Referring now to Fig. 1B at step 209, and Fig. 10, focus tilt values θ_x , and θ_y are calculated. Since variables D_y , the distance between the upper measurement site and the lower measurement site, $F2_y$, the average upper focus, and $F1_y$, the average lower focus are known, a trigonometric relationship 905 such as that illustrated in Fig. 10, is applied to calculate the angle, θ_y of the y tilt which is $\arctan y/x$, and which resolves to:

$$\theta_y = \arctan((F2_y - F1_y)/D_y) * (Pi/180) * 1E6 \text{ microradians.}$$

25 Similarly, by a 90° rotation of the trigonometric relation 905 in Fig. 10, the relationship $\arctan y/x$ is maintained for the angle, θ_x of the x tilt, and is calculated from D_x , the known distance between the left and right measurement sites, $F2_x$, the average right focus, and $F1_x$, the average left focus as follows:

$$\theta_x = \arctan((F2_x - F1_x)/D_x) * (Pi/180) * 1E6 \text{ microradians.}$$

5

For both θ_x and θ_y the $(\pi/180)*1E6$ factor is used to convert the θ angles from degrees to microradians, a common unit of measurement used in exposure tools.

Returning to Fig. 1B, at step 210, similar to the check for Zbias, a check of the tilt offsets, θ_x and θ_y is performed. If any of these values are outside of a predetermined limit, further adjustments are halted and the job is flagged for rework.

The preferred methods of the present invention can also be used to indicate problems with the focusing system on a photolithographic exposure tool. For example, if the focusing system on a malfunctioning tool is not properly compensating for changes in the barometric pressure, such an error can be seen in the standard tool focus checks on monitor wafers as a change in z focus with barometric pressure. As shown in Fig. 11, linear regression of the raw data points 1101 of this z focus change with barometric pressure yields the relationship indicated by line 1102. Additionally, 3D line edge width measurements can also detect the problem on standard product measurements as indicated by points 1201 in Fig. 12, where Edge width varies as a function of barometric pressure. Linear Regression, line 1202, indicates the edge width varying as a function of barometric pressure. The use of EW vs. pressure trend for a tool check center of focus results in an advantage over standard monitor tool checks because the mean time to detect a problem is smaller with the EW technique.

A computer with non-volatile, i.e. hard drive, storage capability 1410 is provided for performing profile and line edge calculations required to produce z focus and x/y tilt settings. The storage is used for maintaining a database 1460 with the relevant across field line width variation information stored therein, including but not limited to Lower Left, Lower Right, Upper Left, and Upper Right imaged photoresist critical dimensions. Additionally Average Upper EW, Average Lower EW, Average Right EW, and Average

5 Left EW are computed and stored for data processing which will result in an actual x/y tilt of the exposure field plane. The computer calculates and stores an empirically derived equation from which the edge width number is translated into an actual focus measurement.

10 Thus, the preferred method of the present invention can achieve target CD by measuring line edge width and contact hole space variations in resist profile, then relating the variations to changes in focus wherein a function is defined for computing a focus correction thereby allowing feed back of the focus correction to the stepper tool being used.

15 While this invention has been particularly shown and described with respect to preferred embodiments thereof, it will be understood by those skilled in the art that the foregoing and other changes in form and detail may be made without departing from the spirit and scope of the present invention. It is therefore intended that the present invention not be
20 limited to the exact forms described and illustrated, but fall within the scope of the appended claims.
